Abstract

We analyze the existed solar neutrino experiment data and show the allowed regions. The result from SNO's salt phase itself restricts quite a lot the allowed region's area. Reactor neutrinos play an important role in determining oscillation parameters. KamLAND gives decisive conclusion on the solution to the solar neutrino puzzle, in particular, the spectral distortion in the 766.3 Ty KamLAND data gives another new improvement in the constraint of solar MSW-LMA solutions. We confirm that at 99.73% C.L. the high-LMA solution is excluded.

I Introduction

The electron neutrinos emitted from the sun disappear somewhere when they travel to the earth. This is the famous solar neutrino deficit, which is the almost forty years' "Solar Neutrino Problem". There were many attempts to solve this puzzle during the years. Some of them were tried to modify the solar model in order to give a lower original neutrino flux, which conflict the energy spectrum provided by the 4 first-generation experiments: Homestake, Sage, Gallex and Kamiokande [1, 2, 3, 4]. Recent experiments have shown that the solar neutrino oscillate by $\nu_e \rightarrow \nu_{\mu,\tau}$ inside the sun via MSW conversions. This was proven by the Sudbury Neutrino Observatory (SNO) [5], and it was confirmed by the reactor experiment KamLAND [6]. The former experiment detects ν_e , $\nu_e + \nu_\mu + \nu_\tau$ and $\nu_e + 15\%(\nu_\mu + \nu_\tau)$ three quantities on earth, which correspond to CC, NC and ES interactions respectively; KamLAND observes $\bar{\nu}_e \rightarrow \bar{\nu}_x$ neutrino oscillation channel.

II Solar neutrinos

The solar neutrino puzzle was solved by the neutrino oscillations $\nu_e \rightarrow \nu_{\mu,\tau}$ inside the sun via MSW conversions. This was proved by the Sudbury Neutrino Observatory (SNO) in Canada. And it was confirmed by the laboratory base line experiment KamLAND in Japan.

SNO is a 1000 ton heavy water Cerenkov detector mainly measuring 8B solar neutrinos. It consists of nearly 9450 photon-multiplier tubes and light concentrator units arrayed on a geodesic support structure, with light water surrounding the spherical acrylic vessel containing the D_2O . The first phase of SNO data is from the pure D_2O . After that the experimenters add up $NaCl$ (salt)

to enhance the NC events rates. This is called the second phase or "salt phase".

In analysis of the solar oscillation data [7], we use the χ^2 defined as:

$$\chi_{\otimes}^2 = \chi_{1gen}^2 + \chi_{SK}^2 + \chi_{SNO}^2, \quad (2.1)$$

where χ_{1gen}^2 stands for Chlorine and Gallium experiments. To calculate each individual chi square in the right hand side of eq. (2.1), we use the so called covariance approach:

$$\chi_{covar}^2 = \sum_{n,m=1}^N (R_n^{\text{exp}} - R_n^{\text{theo}}) [\sigma_{nm}^2]^{-1} (R_m^{\text{exp}} - R_m^{\text{theo}}). \quad (2.2)$$

Here R_n^{exp} and R_n^{theo} correspond to experimental result and theoretical value for the n-th data point. N=2,34,44 are for χ_{1gen}^2 , χ_{SK}^2 , χ_{SNO}^2 respectively. For getting a R_n^{theo} , the important step is to calculate the ν_e survival probability. We have used three methods to check its consistency: the Parke formula [8]; the modified semi-analytic formula in [9]; and the completely numerical propagation. We found that the second way is the best, considering both the calculation precision and the computer CPU hour.

The covariant matrix of squared error σ_{nm}^2 can be written as

$$\sigma_{nm}^2 = \delta_{nm} \mu_n \mu_m + \sum_{k=1}^K c_n^k c_m^k. \quad (2.3)$$

μ_n is the uncorrelated error of the n-th detected quantity for both the experiment and the theory (such as the statistic uncertainty, or other uncertainties which affect only one detectable value), and c_n^k is the correlated systematic error caused by the k-th correlated original error (the original error may be the spectrum uncertainty, or the energy resolution uncertainty, etc.). For a detectable

value R_n^{exp} , we can say that its uncertainty ($R_n^{\text{exp}} - R_n^{\text{theo}}$) is in the range of $\pm\mu_n \pm c_n^1 \pm c_n^2 \pm \dots \pm c_n^k$.

For $\chi_{1\text{gen}}^2$, the correlated errors are the 12 SSM uncertainties X_i (the cross section factors $S_{11}, S_{13}, S_{34}, S_{1,14}, S_{17}$; the ${}^7\text{Be}$ capture cross section C_{Be} ; the solar luminosity; metallicity Z/X ; age; opacity; the element diffusion and S_{hep}), whose relative uncertainties $\Delta \ln X_k$ determine the correlated uncertainties of the neutrino fluxes Φ_i^{SSM} through the logarithmic derivatives

$$\alpha_{i,k} = \frac{\partial \ln \Phi_i^{\text{SSM}}}{\partial \ln X_k} \quad (2.4)$$

With this uncertainties and the matrix given in (2.3) (2.4), we can calculate the fractional uncertainties of the SSM neutrino fluxes:

$$\Delta \ln \Phi_i^{\text{SSM}} = \sqrt{\sum_{k=1}^{12} (\alpha_{i,k} \Delta \ln X_k)^2}$$

For χ_{SNO}^2 and χ_{SK}^2 , the only effective SSM uncertainty is the ${}^8\text{B}$ neutrino flux uncertainty since the hep neutrino flux is too small. So, we use free ${}^8\text{B}$ flux method [10], i.e., we float the flux near the central value given in paper [11] within 1σ uncertainty range, then find out which flux gives the minimal χ^2 . The χ^2 formula changes a little as

$$\chi^2 = \sum_{n,m=1}^N (R_n^{\text{exp}} - f_B \cdot R_n^{\text{theo}}) [\sigma_{nm}^2]^{-1} (R_m^{\text{exp}} - f_B \cdot R_m^{\text{theo}}) + \frac{(1 - f_B)^2}{\sigma^2}.$$

Thus to describe σ_{nm}^2 in these two experiments, we don't need to consider the SSM uncertainties. The remaining original uncertainties that can affect χ_{SK}^2 are the ${}^8\text{B}$ spectrum shape error, the energy scale uncertainty, the resolution uncertainty and an overall SK systematic offset uncertainty. For SNO, the remaining original uncertainties are ${}^8\text{B}$ spectrum shape error, the energy

scale uncertainty, the resolution uncertainty, the vertex reconstruction uncertainty, the cross section uncertainty, the neutron capture uncertainty, the neutron background uncertainty, and low energy background uncertainty [5].

Using this method we scan the solar neutrino $\tan^2 \theta_{12} - \Delta m_{12}^2$ parameter space, neglecting the tiny correction from θ_{13} and Δm_{13}^2 . The allowed regions are shown in figs. 1.

III Manufactured neutrinos

At present the only detected laboratory neutrinos which are sensitive to $\Delta m_{12}^2 - \tan \theta_{12}$ parameters are reactor neutrinos. KamLAND is a first experiment to deal with these solar neutrino parameters completely from manufactured source instead of from the sun. This reactor neutrino experiment convinces scientists that the Large Mixing MSW is the solution of the solar neutrino problem [10, 12, 13].

In a reactor, anti neutrinos are released by radioactive isotope fission; the total neutrino spectrum is a rather well understood function of the thermal power W , the amount of thermal power w_i emitted during the fission of a given nucleus, and the isotopic composition of the reactor fuel f_i ,

$$S(E_\nu) = \frac{W}{\sum f_i w_i} \sum f_i \left(\frac{dN}{dE_\nu} \right)_i \quad (3.1)$$

The index i of f_i stands for 4 isotopes such are ^{235}U , ^{238}U , ^{239}Pu and ^{241}Pu . The (dN/dE) is the energy spectrum of the fissionable isotope, it can be parameterized by the following expression[14] when $E_\nu \geq 2\text{MeV}$:

$$\frac{dN_\nu}{dE_\nu} = e^{a_0 + a_1 E_\nu + a_2 E_\nu^2} \quad (3.2)$$

the coefficients a_i depend on the nature of the fissionable isotope. KamLAND is a scintillator detector, where electronic anti neutrinos are detected by free protons via inverse β -decay reaction[14],

$$\bar{\nu}_e + p \rightarrow e^+ + n \quad (3.3)$$

in the limit of infinite nucleon mass, the cross section of this reaction is given by $\sigma(E_\nu) = k E_{e^+} P_{e^+}$, where E_{e^+} , P_{e^+} are the positron energy and momentum respectively and k can be taken as $k = 9.55 \times 10^{-44} \text{ cm}^2/\text{MeV}^2$. The anti neutrino events are characterized by the positron annihilation signal and the delayed neutron capture sign [6].

From the reactor to the detector, massive neutrinos oscillate on the way and change their flavor composition to a certain extent. The anti neutrino, $\bar{\nu}_e$, can oscillate to other flavors via Δm_{12}^2 and Δm_{13}^2 . For KamLAND experiment, the distance is in the range of hundred kilometers. Due to the

Figure 2: The combined LMA region of solar and KamLAND data before conference Nu2004. The difference between left and right shows improvement from SNO's salt phase result. The confidence levels are the same as what in fig. 1.

tiny value of θ_{13} and the value of Δm^2_{13} , contribution to oscillation from the biggest neutrino mass scale m_3 gives a small averaged effect thus we can reduce it to a two-flavor neutrino analysis:

$$P(E_\nu, L, \theta_{12}, \Delta m^2_{12}) = 1 - \sin^2(2\theta_{12}) \sin^2 \left(\frac{1.27 \Delta m^2_{12} (\text{eV}^2) L(\text{m})}{E_\nu (\text{MeV})} \right) \quad (3.4)$$

The combined results of solar and reactor neutrino experimental data before "Neutrino 2004" are shown in figs. 2.

Using the newest 766.3 Ton-Year of data published by KamLAND collaboration at conference *Neutrino 2004*, we find the $\tan^2 \theta_{12} - \Delta m^2_{12}$ allowed region with the energy spectrum in 13 bins. The result is shown in fig. 3 -left. The combined chi square is then $\chi^2 = \chi^2_{\otimes} + \chi^2_{KL}$ with result shown in fig. 3 -right; which confirms the Large Mixing Angle MSW solution to the solar neutrino problem. The best fit point we get is

$$\tan^2 \theta = 0.4; \quad \Delta m^2_{21} = 8.3 \times 10^{-5} \text{eV}^2,$$

Figure 3: Left is the new KamLAND allowed regions for 766.3 Ty data, together with the LMA solution contours (not filled in) by solar neutrinos themselves. Right is the combined LMA region of solar and KamLAND data. The confidence levels are the same as what in fig. 1.

which is consistent with the previous papers [15]; The day-night effect [16] for solar neutrinos is then expected to be about two to four percent.

Many other possible candidates for the solution of solar neutrino problem are excluded; sterile neutrinos are no more supported in this long-lasting puzzle. However, the most reliable candidate, the LMA MSW solution is becoming precise and more confident in terms of a much larger confidence level and much smaller allowed region. Thus we conclude that the solar neutrino problem is solved by large mixing MSW solution, with parameters shown in fig. 3.

In conclusion, using the new data of KamLAND experiment we conclude that the solar neutrino solution is in the large mixing MSW adiabatic allowed region, corresponding to $(\tan^2 \theta, \Delta m^2) \sim (0.27 - 0.62, 7.2 \times 10^{-5} - 9.5 \times 10^{-5} eV^2)$, at 4σ level. Which is an amazing small region in the parameter space with such a high confidence level. Our result with best fit point at $(\tan^2 \theta, \Delta m^2) \sim (0.4, 8.3 \times 10^{-5} eV^2)$ is in good agreement with previous studies. Predictions of the MSW adiabatic

conversion solution of the neutrino energy spectrum, the day-night effect, the seasonal variation, the ratio of CC and NC current events are all consistent with the solar data. At present, none signal indicates other solutions rather than the MSW adiabatic solution, together with the standard solar model.
